Abstract. The crisis of the cold dark matter and problems of the self-interacting dark matter models is resolved by postulating flavor mixing of dark matter particles. Flavor-mixed particles segregate in the gravitational field to form dark halos composed of heavy mass eigenstates. Since these particles are mixed in the interaction basis, elastic collisions convert some of heavy eigenstates into light ones which leave dense central regions of the halo. This annihilation-like process will soften dense central cusps of halos. The proposed model accumulates most of the attractive features of self-interacting and annihilating dark matter models, but does not suffer from their severe drawbacks. This model is natural; it does not require fine tuning.

INTRODUCTION

Dark matter constitutes most of the mass in the Universe, but its nature and properties remain largely unknown. A model of structure formation in a universe with cold dark matter (CDM) is in excellent agreement with observations on large scales (\gg Mpc) which, thus, supports the hypothesis that dark matter particles are heavy and weakly interacting with baryonic matter and photons, while on small (galactic and sub-galactic scales) it appears to be in conflict with recent observations. This fact suggests that the CDM model is a good first approximation, but it has to be corrected on a galactic scale.

The simplest and most popular models are the self-interacting dark matter (SIDM) [1] and the annihilating dark matter (ADM) [2]. There are some problems with each. In a simplest SIDM, the scattering cross-section of dark matter (DM) particles, σ_{si} , must be such that to ensure that the flat core forms just by now; larger σ_{si} result in core collapse and cuspy cores while for smaller σ_{si} the core flattening time is larger than the Hubble time. Moreover, it seems difficult to obtain flattened cores in galaxies and in clusters by the same time because of very different dynamical scales. The ADM model suffers from the severe “annihilation catastrophe” in the early universe (unless some *ad hoc* assumptions made). Here we present a natural model which has all attractive features of these both models but does not suffer from their drawbacks.

SIDM MODEL WITH QUANTUM MIXING

For the sake of simplicity, let us assume that there exist two flavors, the strongly self-interacting, $|\mathcal{I}\rangle$, and the non-self-interacting or “sterile”, $|\mathcal{S}\rangle$, ones. Each of these interaction eigenstates is a superposition of two mass eigenstates, the “heavy”, $|M\rangle$, and the “light”, $|m\rangle$, ones. We write

$$\begin{pmatrix} |M\rangle \\ |m\rangle \end{pmatrix} = \begin{pmatrix} \cos \vartheta & \sin \vartheta \\ -\sin \vartheta & \cos \vartheta \end{pmatrix} \begin{pmatrix} |\mathcal{I}\rangle \\ |\mathcal{S}\rangle \end{pmatrix}, \quad (1)$$

where ϑ is the mixing angle. Throughout the paper, we assume for simplicity that $M \gg m$, so that heavy states are *non-relativistic* and light states are *relativistic*.

The concept of flavor eigenstates arises when interactions of particles are considered. In the field-free theory the particle fields in the mass basis have a physical meaning instead. In general, such mass eigenstates have different momenta and energies, $E_{M,m}^2 = |\mathbf{p}_{M,m}|^2 c^2 + \{M, m\}^2 c^4$. Between the interactions, the mass eigenstates propagate independently, with different velocities $\mathbf{v}_{M,m} = \mathbf{p}_{M,m} c^2 / E_{M,m}$. Thus at times

$$t \gg t_s \sim \delta x / |\mathbf{v}_m - \mathbf{v}_M| \sim \delta x / c, \quad (2)$$

where δx is the spatial width of a wave-packet, these states are separated from each other and their wave functions no longer overlap, as illustrated in Fig. 1a. The separation time above is negligibly small compared to a galactic dynamical time scale. In a gravitational field different eigenstates also segregate by mass. Non-relativistic $|M\rangle$ -states form halos and the large-scale structure (this is CDM) while relativistic $|m\rangle$ -states leave the halo and behave similar to hot DM.

As dark matter halos form, the density in the central parts increases and, at some point, self-interactions of the dark matter particles become important. Let us consider the elementary act of *elastic* scattering of two DM particles, i.e., $|M\rangle$ eigenstates. The initial wave function of two interacting particles in the center of mass frame, according to equation (1), is

$$\Psi_i = (e^{ikz} \pm e^{-ikz}) |M\rangle = e^{\pm ikz} (\cos \vartheta |\mathcal{I}\rangle + \sin \vartheta |\mathcal{S}\rangle), \quad (3)$$

where “+” corresponds to Ψ_i symmetric to interchange of particles (integer total spin) and “−” – to an antisymmetric Ψ_i (half-integer total spin), the exponents represent two waves, propagating to the right and to the left, and $e^{\pm ikz} \equiv (e^{ikz} \pm e^{-ikz})$ is the short-hand notation. For scattering, the interaction basis is appropriate, rather than the mass basis, hence the expansion above. During the scattering event, only $|\mathcal{I}\rangle$ -component is changing, since $|\mathcal{S}\rangle$ -component does not interact. The wave function after scattering at large distances thus becomes

$$\begin{aligned} \Psi_s &\approx \left(e^{\pm ikz} + \frac{f_{\pm}(\theta)}{r} e^{ikr} \right) \cos \vartheta |\mathcal{I}\rangle + e^{\pm ikz} \sin \vartheta |\mathcal{S}\rangle \\ &= \left(e^{\pm ikz} + \cos^2 \vartheta \frac{f_{\pm}(\theta)}{r} e^{ikr} \right) |M\rangle - \cos \vartheta \sin \vartheta \frac{f_{\pm}(\theta)}{r} e^{ikr} |m\rangle, \end{aligned} \quad (4)$$

where the combination $f_{\pm}(\theta) = f(\theta) \pm f(\pi - \theta)$ arises because particles are indistinguishable and $f(\theta)$ is the amplitude of scattering of flavor states. The radial part of the wave function represents a diverging scattered wave. One can clearly see that an initial heavy eigenstate acquires, upon scattering, a light eigenstate admixture. In other words, a heavy eigenstate may be converted into a light eigenstate. This process is illustrated in Fig. 1b. The differential cross-section of a process is the scattering amplitude squared. Integrating over θ we have the relation between the scattering and conversion cross-sections:

$$\sigma_{conv} = \tan^2 \vartheta \sigma_{si}. \quad (5)$$

The rest is straightforward. The light particles escape from the halo core and decrease its density. This prevents core collapse even if the scattering time is much smaller than the Hubble time. In this respect, the proposed model resembles an ADM model. However, no annihilation occurs in the dense early Universe because forward conversions of M 's into m 's are balanced by the reverse ones of m 's into M 's. A more detailed discussion of the process of freeze-out of mixed DM particles and the resultant constraints on the model will be presented elsewhere.
